

This lecture marks our full entry into integer data structures (though hashing was also one), as well as our first of three lectures on the predecessor problem: supporting insert, delete, and predecessor/successor on a set of n w -bit integers. I'll give an overview of what's known about this problem, as well as the appropriate models of computation, and then proceed to the first main result: data structures achieving $O(\lg w)$ time per operation. When w is polylogarithmic in n (a common case), this bound is $O(\lg \lg n)$, an exponential improvement over binary search trees. The first such data structure is called (and by) van Emde Boas, and it uses $\Theta(2^w)$ space. A little addition of hashing reduces the space to optimal $\Theta(n)$. We'll also see simpler ways to achieve the same bounds, using a simple tree view, indirection, and structures called x -fast and y -fast trees by Willard (who was actually the first to get $\Theta(n)$ space).
